Mehrdad Behmanesh*^{1, 4}

Abstract

Background: One of the major challenges in gene therapy is producing gene carriers that possess high transfection efficiency and low cytotoxicity (1). To achieve this purpose, crystal nanocellulose (CNC) -based nanoparticles grafted with polyethylenimine (PEI) have been developed as an alternative to traditional viral vectors to eliminate potential toxicity and immunogenicity.

Methods: In this study, CNC-PEI10kDa (CNCP) nanoparticles were synthesized and their transfection efficiency was evaluated and compared with linear cationic PEI10kDa (PEI) polymer in HEK293T (HEK) cells. Synthesized nanoparticles were characterized with AFM, FTIR, DLS, and gel retardation assays. *In-vitro* gene delivery efficiency by nano-complexes and their effects on cell viability were determined with fluorescent microscopy and flow cytometry.

Results: Prepared CNC was oxidized with sodium periodate and its surface cationized with linear PEI. The new CNCP nano-complex showed different transfection efficiencies at different nanoparticle/plasmid ratios, which were greater than those of PEI polymer. CNPC and Lipofectamine were similar in their transfection efficiencies and effect on cell viability after transfection.

Conclusions: CNCP nanoparticles are appropriate candidates for gene delivery. This result highlights CNC as an attractive biomaterial and demonstrates how its different cationized forms may be applied in designing gene delivery systems.

Keywords: Crystal Nanocellulose, Gene transfection, Nanoparticle, Nano-complex.

Introduction

Only about 7% of human diseases are treatable with the estimated 10,000 drugs available on the market (2). While a large portion of available drugs offers temporary relief from disease-related symptoms, gene therapy provides long-lasting therapeutic protein production in patients by delivering functional genes (3). The potential becomes more interesting when considering that 80% of human diseases are associated with dysfunctional genes. However, safe and efficient

gene therapy techniques are in the developmental stage. Whatever the target gene, it should be cloned and loaded on a proper vehicle to be expressed and encounter the disorder at its source. Viral vector-based systems such as retroviruses, adenoviruses, and adeno-associated viruses have demonstrated superior transfection efficiencies and have been widely studied for gene delivery purposes (4, 5). Despite significant successes, the life-threatening potential of viral

vectors is a limiting factor. These systems may cause important safety issues including immunogenicity and carcinogenicity, and they have high setup costs. Consequently, non-viral vectors have received considerable attention due to their safety, stability, and cost-effectiveness. However, gene therapy researchers aim at refining them in some aspects including toxicity and transfection rate (6, 7). In the pursuit of this approach, cellulose, an abundant and biodegradable biomaterial, has been an attractive source used in gene delivery systems (8). Among various derivatives that have been used for this purpose, including hydroxyethyl cellulose (HEC), hydroxypropyl cellulose (HPC), carboxymethyl cellulose (CMC), and hydroxypropyl methyl cellulose (HPMC) (9), crystal nanocellulose (CNC) has also been investigated as a nontoxic gene delivery system. To be used as a vector, needle-like CNC must be modified with a cationic polymer to be able to condense negatively-charged DNA into compact nano-complexes (10). The cationic polymer also decreases the electrostatic repulsion between cell surfaces and DNA, protects plasmid DNA from enzymatic degradation by nucleases, and accelerates cellular transfection. Polyethylenimine, a cationic polymer available in various sizes and shapes, has also been widely used for gene delivery systems alone or complexed with CNC to form nano-complexes. However, polyethylenimine toxicity is the main impediment to its clinical use (11, 12).

Increased polyethylenimine (PEI) molecular weight increases transfection efficiency; however, increased molecular weight also increases cytotoxicity. Most polyethylenimines used for gene delivery are highly branched, mainly because linear polyethylenimine has low DNA-condensing efficiency, despite its lower cytotoxicity (13, 14). This study is the first to investigate whether a high molecular weight (10 kDa) linear polyethylenimine, complexed with CNC as a biomaterial, could provide a balance of transfection efficiency and biocompatibility. Our results demonstrate that this new nanoparticle, fabricated from surface-modified CNC with linear PEI, is superior to PEI in both

transfection efficiency and subsequent cell viability. Furthermore, this new nanoparticle, at its optimum nanoparticle/plasmid (N/P) ratio, provides transfection efficiency close to, and performs better in cell viability rate, than Lipofectamine. These findings, along with CNC's natural abundancy, showcase it as a promising category of non-viral nanocarriers.

Materials and methods

PEI10kDa, Propan-1-ol, NaIO₄, and NaBH₃CN were purchased from Sigma Aldrich. FBS, trypsin, penicillin-streptomycin mixture, L-glut, Lipofectamine 2000, and APCcy7 were purchased from Invitrogen Life Science Technologies Company. EZ-Vision dye was obtained from VWR, HEK cells were kindly provided by Dr. Ashkar Lab at McMaster University, and pmaxGFP™ plasmid was supplied by Lonza Company.

Cellulose nanocrystal preparation

CNCs were prepared according to the method of Morandi and Vincent (15, 16). Briefly, 5 g of pulp sheet were dispersed in sulfuric acid and incubated at 45 °C for 35 min. Precipitates were washed 3 times by centrifugation at 15,000 rcf and 10 °C for 20 min, and then dialyzed for 1 week. The suspensions were filtered via a nylon mesh to remove residual aggregates, lyophilized, and oxidized with sodium periodate. To avoid cellulose super-oxidation, propan-1-ol was added. The mixtures were stirred for 4 days at room temperature in the dark, and the residual periodate was quenched by adding ethylene glycol to the reaction. The oxidized CNC was purified by dialyzing for 2 days against distilled water using a dialysis tube (Mw cut-off 8,000 Da).

CNCP nanoparticle synthesis

Oxidized CNCs (10 mg) were reacted with 2 mg of PEI10kDa at neutral pH. Then NaBH₃CN (2.5 mg) was added followed by mild mechanical stirring for 24 h at room temperature in the dark. After this reaction, CNCP nanoparticles were purified by centrifugation 2 times at 10,000 rcf for 10 min, and lyophilized.

Complexation of pmaxGFPTM plasmid with CNC
CNC nanoparticles (1 mg/mL) in ultrapure water were sonicated for 30 min. Plasmids of pmaxGFPTM (0.25 nmol, 3 µg) were added to CNC nanoparticle solutions at concentrations of 0.25 to 1 mg. Final volumes were adjusted to 1 mL with PBS. Solutions were stirred at 250 rpm for 30 min and centrifuged at 17,000 rcf for 10 min. The supernatants were discarded and the pellets containing pmax-CNC-PEI (pCNC) resuspended in 250 µL of 1X PBS. The free DNA amount in the supernatant was determined using a Nanodrop (GE NanoVue). The DNA amounts bound to CNC were calculated by subtracting free DNA amounts in the supernatant from total DNA introduced into the sample.

Agarose Gel Electrophoresis Assay

pCNC complexes with N/P ratios of 1, 5, 10, and 20 were prepared by adding an appropriate volume of CNC in 0.15 M NaCl solution to 500 ng of pmaxGFPTM plasmid. The complexes were incubated at 37 °C for 30 min and then electrophoresed on a 1% (W/V) agarose gel containing EZ-Vision dye and with 1X Tris-acetate-EDTA (TAE) running buffer at 90 V for 60 min. DNA was visualized with a UV lamp using an Alpha Imager imaging system.

Zeta potential and particle size

The zeta potentials and z-average particle sizes of the freshly-prepared CNCs, CNCs, and pCNC complexes were measured using a Malvern Zetasizer Nano instrument. The nanoparticle samples were diluted to 0.1 wt% in Milli-Q water at 25 °C. The recorded zeta potentials were averages of 12 measurements.

Fourier transform-infrared spectra (FTIR)

Samples' FTIR spectra were collected with a transmission FTIR spectrometer (Perkin Elmer) using single bounce diamond attenuated total reflectance (ATR) accessory. Solid samples were placed directly on the ATR crystal, and all the measured sample spectra were averaged from 16 scans from 500 to 4,000 cm⁻¹ with a resolution of 4 cm⁻¹.

Atomic force microscopy (AFM) measurement

Particle morphological properties were investigated by AFM (Nanoscope IIIa MultiMode with

Extender, Veeco Metrology Group, Santa Barbara, CA). Typically, freshly-cleaved mica was pre-coated with poly-L-lysine, a drop of sample was placed on the treated mica surface for 10 min, the excess sample was rinsed off with milli-Q water, and air-dried before measurements. The experiments were performed in tapping mode with silicon cantilevers (ACTA model, AppNano) using a nominal spring constant of 37 N/m, a nominal resonant frequency of 300 kHz, and a nominal tip radius of 6 nm. Nanoscope analysis of 1.4 was used to process the AFM images.

Cell culture and transfection

HEK cells, cultured in DMEM medium supplemented with L-glutamine, 10% (v/v) FBS, 100 units/mL penicillin and 100 µg/mL streptomycin were maintained at 37 °C in a humidified incubator containing 5% CO₂ in air.

In vitro transfection of HEK cells

To examine green fluorescent protein (GFP) expression and cellular uptake of pCNC nanoparticles, HEK cells were seeded at 7×10^4 cells/well in a 24-well plate with 1 mL DMEM containing 10% FBS and incubated at 37 °C for 24 h. When the cells reached 80–90% confluency, they were washed with PBS, and then pCNC nanoparticles were added. At this step 1 ml/well of serum-free culture medium was added. Each well received 2 µg of DNA. Naked DNA was used as a negative control. Lipofectamine 2000 was used as positive control following the manufacturer's protocol. The plates were incubated at 37 °C for 6 h, the cell media was removed and replaced with 1 mL of complete media, and cultures were incubated for 42 h.

Fluorescence microscopy

To visualize the pmaxGFPTM transfection, 48 h after transfection, expression of the enhanced green fluorescent protein in HEK cells was evaluated by fluorescence microscopy (EVOSTM FL Imaging System). The bright-field and overlay images of transfected HEK cells were also prepared to observe the transfected HEK cell morphology. The images were recorded at 4X (400 µm) magnification.

Flow cytometry

After transfection, GFP expression and HEK cell viability were determined and calculated by flow cytometry. HEK cells were trypsin zed and plated into 96-well plates at 2×10^5 cells/well and then washed with 200 μL of PBS. The plate was then centrifuged at 450 rcf for 5 min at 4 °C, and the supernatant discarded. Then, 100 μL of Fixable Viability Dye (APCcy7) was added to each well and the plate was incubated at 4 °C for 30 min in the dark. The plate was centrifuged and washed with 100 μL of FACS buffer. The cells were fixed with 1% paraformaldehyde and the plate was placed at 4 °C in the dark for 1 h. The plate was centrifuged and cells were resuspended in 100 μL of FACS buffer for flow cytometry analysis.

Statistical Analysis

All experiments were performed in triplicate and data is shown as means \pm standard deviations of these repeats. The Student's t test was used to assess statistical significance and differences

were reported as significant for * $p < 0.05$, and highly significant for ** $p < 0.01$.

Results

Preparation of CNC and CNCP

CNC was obtained from hydrolysis of pulp sheets using 64% sulphuric acid (16). As a result of sulphate groups presence, negatively charged surface of CNC was produced as confirmed by dynamic light scattering (DLS) analysis. To covalently conjugate PEI to CNC, oxidized CNC was prepared by sodium periodate. Propan-1-ol was added to the reaction to prevent super oxidation of CNCs. Subsequently, the oxidized CNC surface was reacted with PEI by adding NaBH_3CN (17).

Zeta potential and particle size

The average CNC surface zeta potential and size were -44.8mV and 210 nm, respectively (Table 1). By grafting PEI onto the CNC surface, the nanoparticle zeta potential and size increased to 34.2 mv and 324 nm respectively, resulting from the amine group presence (18).

Table 1. CNC and CNCP nanoparticles were diluted to 0.1 wt% in Milli-Q water at 25 °C and their zeta potentials and particle sizes measured on a Malvern Zetasizer Nano instrument.

	Zeta potential distribution of CNC (mv)	Average size of CNC (nm)
CNC	-44.8 \pm 1.3	210 \pm 12
CNCP	34.2 \pm 0.3	324 \pm 2.12

The complexation of CNCP nanoparticles with pmaxGFPTM plasmid (pCNCP) in different N/P ratios caused the zeta value to increase gradually as the N/P ratio increased from 1 to 20, and this positive charge was not affected at N/P ratios of 20 and above (Fig. 1a). As the N/P ratios increased from 1 to 5, the pCNCPs decreased in size and then increased as the ratios rose from 5 to 20; however, the size was greatest at an N/P ratio of 1 (Fig. 1b).

Fourier Transform Infrared spectroscopy (FTIR)

FTIR was used to chemically characterize the CNC before and after surface modification (Fig. 2). A broad band from 3500 to 3200 cm^{-1} in

CNC spectrum was due to the stretching of the -OH groups (16). The peak at 2892 cm^{-1} was assigned to C-H symmetrical bending and provided the evidence of containing cellulose (19). The peak around 1745 cm^{-1} was a characteristic of carbonyl stretching at the aldehyde group (20). The peaks at 1430 cm^{-1} were assigned to CH_2 scissoring. The peaks at 1371 cm^{-1} and 1319 cm^{-1} were due to C-H bending vibrations and C-O bonds in aromatic rings of polysaccharide, respectively (21). The peak at 894 cm^{-1} was a result of rocking vibrations of CH_2 groups in the cellulose (22). By using NaBH_3CN and reductive amination, PEIs were grafted onto oxidized CNC. A peak at 1485 cm^{-1} was produced in the spectra of

CNCP, which corresponded to NH_3^+ groups (Fig 2a). The peaks of primary and secondary amines in PEI appeared between 3200 and 3500

cm^{-1} (15). Three overlapped peaks belonging to N-H bending vibrations were seen between 1600 and 1660 cm^{-1} (Fig. 2b) (15).

Fig. 1. pmaxGFPTM plasmids (500 ng) were added to solutions with different CNCP nanoparticle concentrations to form solutions with nanoparticle/plasmid (N/P) ratios of 1, 5, 10, and 20. Samples were stirred at 250 rpm for 30 min, diluted to 0.1 wt% in Milli-Q water at 25 °C, and their zeta potentials (a) and particle sizes (b) measured on a Malvern Zetasizer Nano instrument. The average of 3 measurements is shown.

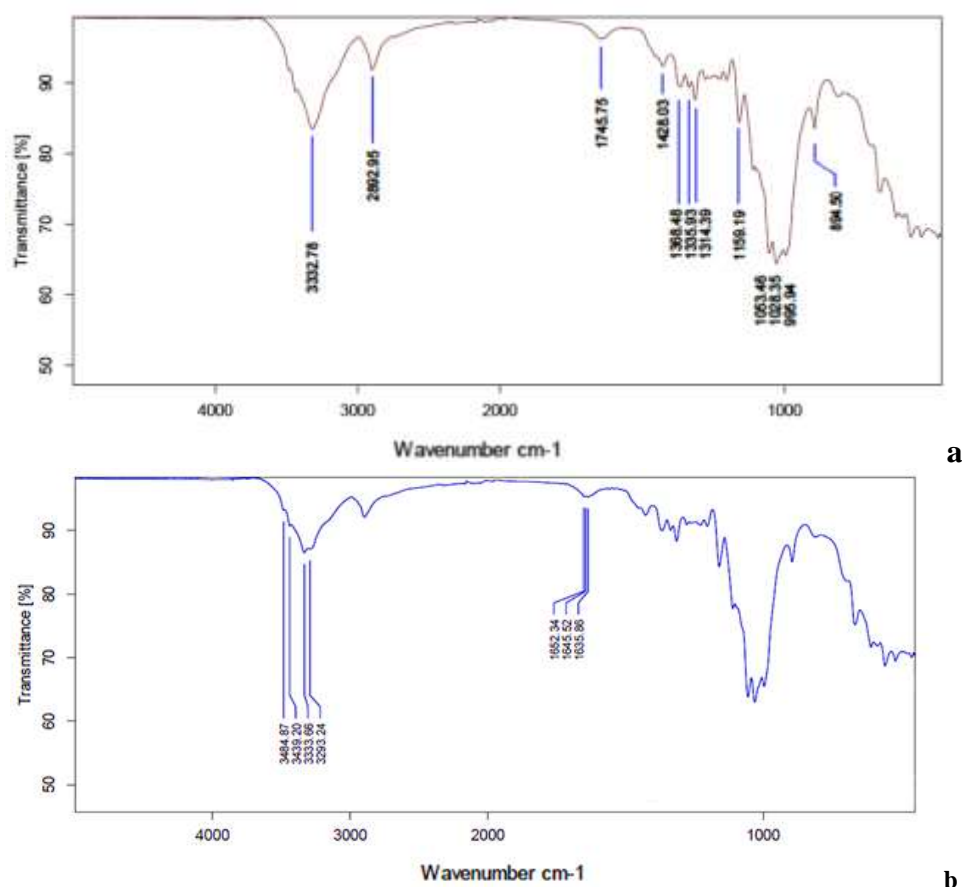

Fig. 2. The FTIR spectra of lyophilised solid samples of (a) CNC and (b) CNCP were measured from 500 to 4,000 cm^{-1} with a resolution of 4 cm^{-1} . The average of 16 scans is shown.

AFM

As determined by AFM imaging, the CNCs contained rod-like particles with lengths of

110–220 nm and diameters of about 10 nm (Fig. 3).

Fig. 3. The morphology of CNCs was visualized by atomic force microscopy (AFM). The AFM was set to tapping mode with silicon cantilevers using a nominal spring constant of 37 N/m, a nominal resonant frequency of 300 kHz, and a nominal tip radius of 6 nm.

Agarose gel electrophoresis

To perform cellular transfection, DNA condensation capability is a critical prerequisite for any nanocarrier; the DNA must be first condensed by cationic nanoparticles to be suitable for cell entry (23). Therefore, agarose

gel electrophoresis was used to confirm the ability of the CNCP to condense pmaxGFP™ plasmid into particulate structures. The pCNCP complex at N/P ratios of 5 or greater inhibited the DNA migration (Fig. 4).

Fig. 4. Electrophoretic mobility of pmaxGFP™ plasmid complexed with CNCP vector at nanoparticle/plasmid (N/P) ratios of 1, 5, 10, and 20. Samples were electrophoresed in a 1.0% agarose gel at 90V for 60 min. Lane 1: naked pmaxGFP™ plasmid and Lanes 2-5: pCNCP nano-complexes prepared at various N/P ratios.

In Vitro Gene Transfection Assay

Pmax-PEI10kDa (pPEI) and pCNCP nano-complexes were prepared at different N/P ratios while maintaining the amounts of pmaxGFPTM plasmid DNA equal to 1 µg/well. Subsequently, the transfection efficiency of pCNCP nanoparticles were compared with those of pPEI nanoparticles, naked pmaxGFPTM plasmid, and Lipofectamine 2000. The transfected HEK cell GFP expression was analyzed by fluorescence microscopy. Forty-eight hours after transfection, no GFP was seen in the naked DNA group (data not shown), while pCNCP nano-complex groups at various N/P ratios and Lipofectamine 2000 produced

green fluorescent cells (Fig. 5). To quantify the transfection efficiency, harvested cells were analyzed by flow cytometry. The transfection efficiency with the pPEI nano-complex increased as the N/P ratio increase from 1 to 20, while with the pCNCP complex, it increased from N/P ratios of 1 to 10 and then decreased at an N/P ratio of 20. Optimal transfection efficiency for pCNCP was obtained at an N/P ratio of 10, which was significantly greater than the optimal transfection efficiency of the pPEI nano-complex at an N/P ratio of 20. The optimal transfection efficiency of pCNCP was similar to that of Lipofectamine 2000 (Fig. 6a).

Fig. 5. HEK cells were transfected with 2 µg of pmax-GFPTM plasmid by incubating them for 6 h with pCNCP nanoparticles at ratios of 1, 5, 10, and 20, or Lipofectamine 2000 (ThermoFisher). 42 h post-transfection cells were imaged using fluorescence microscopy. Fluorescence (top), overlay (middle), and bright-field (bottom) images of green fluorescent protein (GFP) expression in HEK cells are shown.

Cell Viability Assay

To develop a proper vehicle with high efficacy for gene delivery an important factor to consider is its degree of cell toxicity. The cell viability after treatment with pCNCP and pPEI was evaluated in HEK cells at various

N/P ratios by flow cytometry. We found that with increasing N/P ratios the cell viability after treatment with pCNCP and pPEI was decreased; however, the viabilities in the pCNCP nanoparticle-treated groups were

significantly greater than those treated with the pPEI nanoparticles at all N/P ratios. Of significance, at an N/P ratio of 10, the pCNC

nanoparticle-treated cells demonstrated significantly greater viability than those treated with Lipofectamine 2000 (Fig. 6b).

Fig. 6. HEK cells were transfected with 2 µg of pmax-GFP™ plasmid by incubating them for 6 h with pmax-PEI and pCNC nanoparticles at ratios of 1, 5, 10, and 20, or Lipofectamine 2000 (ThermoFisher). Gene transfection efficiency (a) and cell viability (b) were quantified via flow cytometry 48 h after transfection. Significant differences are indicated by stars; **: p-value < 1%, ***: p-value < 0.1%, n = 3.

Discussion

Current efforts to generate more efficient vectors than those currently in use for gene delivery in clinical applications have highlighted the importance of biocompatibility and biodegradability in these carriers (16, 24). As a natural product, CNC has been found to be a safe biomaterial for gene delivery (25). In this study we focused on investigating whether prepared nanocarrier from oxidized CNC complexed with linear PEI 10kDa could provide high transfection rate and cell viability in gene delivery.

Physicochemical characteristics of CNC, such as a large surface area and the presence of different functional groups, are key factors that enable CNCs to react with a variety of polymers (10, 23). According to the FTIR spectra of oxidized CNC following periodate oxidation a peak of 1745 cm^{-1} appeared. This peak was related to aldehyde functions and was in equilibrium with hemiacetal groups (26). Therefore, the low signal was likely a result of carbonyl hydration (27). Using the activated aldehyde groups, CNC was complexed with PEI to enable the nanocarrier to condense DNA. The aldehyde peak in the CNCP spectra disappeared after the reductive amination function; however, because of OH peaks overwhelming primary and secondary amine signals in PEI, the amine signals were masked between 3200 and 3500 cm^{-1} (20). The aldehyde groups enable CNCs to be modified by reductive amination, in which aldehyde reacts with amine to form imine following their reduction to secondary amine. To obtain a stable structure between aldehyde-modified CNC and polyethylenimine, an amine reduction of the imine bound group is necessary (28).

Employing polycations to condense polyanionic DNA is an important prerequisite for gene delivery (7, 29). Appearance of the peak at 1485 cm^{-1} was important evidence to confirm PEI was successfully grafted onto the CNC surface to form a polycationic-CNC nanoparticle (30). These surface-aminated CNCs will allow DNA attachment through the amine groups.

To confirm that the particles were nano-sized, DLS was used to characterize molecular aggregation for oxidized CNC and CNCP complexes (31). Due to presence of sulfate

groups the CNC nanoparticles are highly negatively charged. Increasing positive charge on the modified CNCs confirmed successful grafting of PEI onto their surface (18).

Conjugation of pmaxGFP™ plasmid to the CNCP nanoparticles reduced their net charge and increased their size. The CNCP group conferred a higher transfection rate and greater cell viability than the PEI-only group. This significantly greater transfection efficiency of CNCP could be due to the rod shape of the nanoparticle, which has been demonstrated to be more efficient than the spherical shape of PEI-DNA (20, 32). On another level, high gene delivery efficiency could be a result of high cell viability due to decreased toxicity of PEI caused by nontoxic CNC (33).

Cationic-modified nanoparticles have been extensively used in gene delivery; in addition to their transfection efficiency it is important to evaluate the essential biocompatibility characteristics of nanoparticles, such as cell toxicity. In nanocarrier construction the N/P ratio plays a crucial role in influencing both transfection efficiency and cytotoxicity (36, 37). Optimum N/P ratios in nanoparticles are mainly affected by nanoparticle characteristics including net charge, size, and shape. Various studies have shown that different nanoparticles perform best at different ratios (38-40). In our study the optimum N/P ratio of 10 was most probably due to the best balance between the number of amine groups interacting with CNC to decrease the toxicity of PEI and the number of amine groups available to interact with the greatest possible amount of DNA. In agreement with our results, Ping et al also obtained an optimum transfection rate at an N/P ratio of 10 (40).

The higher cell toxicity and lower transfection rates at higher N/P ratios could have resulted from an increasing abundance of free CNCPs, which produce high positive surface charges (41). Particles with high positive surface charges could have strong electrostatic interactions with the negative charge of the cell membrane, destabilizing and disrupting it, thus increasing cell endocytosis and death (42). Additionally, higher N/P ratios can cause DNA-loaded nanoparticles to be highly stable and decrease DNA release in the

cytosol (43). At lower N/P ratios of 1 and 5, the greatest possible amount of DNA was not complexed to the nanocarrier due to insufficient CNCP. Low transfection efficiency may also have been due to formation of loose nano-complexes as a result of lower N/P ratios; in such a situation CNCP could not efficiently condense pmaxGFP™ plasmid into nano-complexes (23).

Polyethyleneimine, with various molecular weights as a cationic polymer, can complex and condense nucleic acids to facilitate their transport into target cells. However, its toxicity is a serious concern due to its tendency to aggregate and adhere to the cell surface (44, 45). To address this issue, in this study, new cellulose-derived nanoparticles were developed for intracellular gene delivery. This novel nanocarrier CNCP consists of cellulose nanocrystals whose surfaces are covalently modified with PEI, a 10 kDa

cationic polymer. Transfection efficiency and biocompatibility of this CNCP nanoparticle significantly outperformed complexes with PEI or naked pDNA alone.

This study not only introduces an efficient novel nanocarrier but also highlights how CNC, an abundant biomaterial, can be used to develop highly efficacious systems for gene delivery. Further studies focusing on complexing CNC with other cationic polymers to design more novel nanocarriers and testing their efficiency in *in vivo* gene delivery would be the next steps to more thoroughly characterize the potential of CNCs in gene transfection.
