Vascular Endothelial Growth Factor from Embryonic Status to Cardiovascular Pathology

Mohsen Azimi-Nezhad*1,2

Abstract

Vascular endothelial growth factor (VEGF) is a multifunctional cytokine with distinct functions in angiogenesis, lymphangiogenesis, vascular permeability, and hematopoiesis. VEGF is a highly conserved, disulfide-bonded dimeric glycoprotein of 34 to 45 kDa produced by several cell types including fibroblasts, neutrophils, endothelial cells, and peripheral blood mononuclear cells, particularly T lymphocytes and macrophages. Six VEGF isoforms are generated as a result of alternative splicing from a single VEGF gene, consisting of 121, 145, 165, 183, 189, or 206 amino acids. VEGF121, VEGF145, and VEGF165 are secreted whereas VEGF183, VEGF189, and VEGF206 are cell membrane-bound. VEGF145 has a key role during the vascularization of the human ovarian follicle and corpus luteum, in the placentation and embryonic periods, and in bone and wound healing, while VEGF165 is the most abundant and biologically active isoform. VEGF has been linked with a number of vascular pathologies including cardiovascular diseases such ischemic heart disease, heart failure, stroke, and diabetes and its related complications. In this review we aimed to present some important roles of VEGF in a number of clinical issues and indicate its involvement in several phenomena from the initial steps of the embryonic period to cardiovascular diseases.

Keywords: Vascular endothelial growth factor (VEGF), Vascular pathogenesis

Introduction

Vascular endothelial growth factor (VEGF) was first characterized as vascular permeability factor (VPF) by Senger et al. (1) in 1983. They reported that this protein promotes extravasation of proteins from tumor-associated blood vessels. VEGF was further characterized in 1989 when two groups independently identified a heparin-binding protein acting as a mitogen specific for endothelial cells. Subsequently, it was revealed that VPF and VEGF are the same protein encoded by a single gene (2, 3). VEGF is a potent mitogen with various functions involved in early stages of embryogenesis to several pathologies through somatic angiogenesis with a unique specificity for vascular endothelial cells (4, 5). In this review we aimed to present some important roles of VEGF in a number of clinical issues and discuss its family, gene, and structure.

VEGF family members, receptors and mode of action

There are five VEGF variants including VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor, all described in mammals, VEGF-E found in Parapoxviridae, and VEGF-F, also called svVEGF-F, for snake venom VEGF found in viper venom, each with structurally similar proteins involved in the regulation and differentiation of the vascular system, particularly in the blood and lymph vessels (4-7). Table 1 shows similarities and differences between the human VEGF family members.

Among these subtypes, VEGF-A has a main role in mediating angiogenic effects (4, 6). VEGF-A binds and activates two receptors on the cell membrane of endothelial cells, namely VEGF receptor-1, also known as VEGFR-1 and Flt-1, and VEGF receptor-2, also known as VEGFR-2, FIK-1, and KDR. These receptors regulate physiologic and pathologic angiogenesis (6). VEGFR-2 is mainly associated with pathological angiogenesis, such as vascular network formation in tumors and diabetic retinopathy. VEGFR-1, however, has a dual role; in embryo it has a negative effect on angiogenesis via isolation of VEGF-A, while in adults it has a main influence on monocytes and endothelial cells that stimulate angiogenesis (4, 6, 9).

**VEGF-A gene, related isoforms, and proteins**
The human VEGF-A gene is organized in eight exons separated by seven introns and is located on chromosome 6p21.1. The coding region spans approximately 14 kb. Alternative exon splicing results in the generation of four isoforms with 121, 165, 189, and 206 amino acids, respectively, after signal sequence cleavage. The four isoforms are referred to as VEGF121, VEGF165, VEGF189, and VEGF206. VEGF165, the predominant isoform, lacks the residues encoded by exon 6, whereas VEGF121 lacks the residues encoded by exons 6 and 7. Less frequent splice variants have been also reported, including VEGF145, VEGF183, VEGF121b, VEGF145b, VEGF165b, and VEGF189b. The variants are reported to have, paradoxically, an inhibitory effect on VEGF induced mitogenesis (6). Figure 1 shows details of the VEGF gene, isoforms, and protein.

Solution of the crystal structure has shown that VEGF forms an antiparallel homodimer covalently linked by two disulfide bridges (6, 10) (Figure 1). This mode of dimerization is similar to that of the PDGF monomers. VEGF121 is an acidic polypeptide that fails to bind heparin. VEGF189 and VEGF206 are highly basic and bind heparin with high affinity. VEGF121 is a freely diffusible protein. In contrast, VEGF189 and VEGF206 are almost completely sequestered in the extracellular matrix.

VEGF165 has intermediate properties, because it is secreted, but a significant fraction remains bound to the cell surface and extracellular matrix. Several studies suggest that VEGF165 has optimal characteristics of both bioavailability and biological potency (4, 6, 10).

**Vasculogenesis and angiogenesis**
The formation of the vascular system is a prerequisite for vertebrate embryogenesis and involves two fundamental processes: vasculogenesis, defined as the differentiation of endothelial cell progenitors and their assembly into the primary capillary plexus, and angiogenesis, the sprouting of new capillaries from pre-existing vessels (6).

**Vascular system in embryonic period**
Induction by fibroblast growth factors of mesoderm during gastrulation leads to blood-forming tissue, including angioblasts and hemopoietic cells, which together constitute the blood islands of the yolk sac. The differentiation of angioblasts from mesoderm and the formation of primitive blood vessels from angioblasts at or near the site of their origin are the two distinct steps during the onset of vascularization that are defined as vasculogenesis. The central role of VEGF in embryonic angiogenesis was illustrated
in heterozygote knock-out mice suffering from fatal deficiencies in vascularization (5). Although vasculogenesis occurs mainly during fetal development, recruitment of angioblasts from bone marrow and peripheral blood in response to ischemic insult has been described in adults (12, 13).

**Vasculogenesis steps and angiogenesis forms**

Vasculogenesis consists of three major steps: induction of hemangioblasts and angioblasts (mediated mainly through fibroblast growth factor (FGF)), assembly of primordial vessels (mediated mainly by vascular endothelial growth factor/vascular endothelial growth factor receptor system, VEGF/VEGFR), and transition from vasculogenesis to angiogenesis (9). Angiogenesis represents the development of new vessels from pre-existing vessels. Two forms of angiogenesis have been described: sprouting and non-sprouting angiogenesis or intussusceptive microvascular growth (intussusception) (14). The sprouting process is based on endothelial cell migration, proliferation, and tube formation. Intussusception divides existing vessel lumens by formation and insertion of tissue folds and columns of interstitial tissue into the vessel lumen (14). Physiologic angiogenesis plays an important role in wound and fracture healing, endometrial growth, embryo implantation, and placenta. In contrast, pathologic angiogenesis underlies pathophysiology of the following conditions: tumor growth and metastasis,
rheumatoid arthritis, retinopathies, chronic inflammation, and psoriasis (15). Therapeutic angiogenesis, defined as the use of biological agents or bioactive materials to stimulate the growth of new blood vessels, was developed for the treatment of ischemic heart disease, cerebrovascular disease, and delayed wound healing (16).

Angiogenesis regulatory factors
Several regulatory factors (Table 3) play a role in angiogenesis. Among them, during angiogenesis, VEGF interacts with several other angiogenic factors and plays an important role in cell proliferation, differentiation, migration, cell survival, nitric oxide (NO) production, and release of other growth factors (7).

Wide implications of VEGF from physiological circumstance to pathological conditions
The ability of VEGF to promote monocyte chemotaxis was the earliest evidence that VEGF can affect blood cells. Subsequently, VEGF was reported to have hematopoietic effects, inducing colony formation by mature subsets of granulocyte-macrophage progenitor cells, regulation of osteoclast differentiation, stimulation of surfactant production, and neurotrophic and neuroprotective effects on neuronal and glial cells. Notably, VEGF infusion to adult mice inhibits dendritic cell development, leading to the hypothesis that VEGF facilitates tumor growth by allowing evasion of tumors from the host immune system. Also, VEGF increased production of B cells and the generation of immature myeloid cells. Some studies suggest that VEGF controls hematopoietic stem cells survival during hematopoietic repopulation (17).

VEGF is also known as vascular permeability factor, based on its ability to induce vascular leakage. The permeability-enhancing activity of this molecule underlies dominant roles in inflammation and other pathological conditions. In accordance with a role in the regulation of vascular permeability, VEGF induces endothelial fenestration in some vascular beds and cultured adrenal endothelial cells (6, 10). Some studies have shown a critical role for nitric oxide (NO) in VEGF-induced vascular permeability, as well as angiogenesis. Fukumura et al. (18) verified the relative contribution of the NO synthase (NOS) isoforms, inducible NOS (iNOS) and endothelial NOS (eNOS), to these processes. Thereby, elevated circulating VEGF has been observed in vascular diseases including ischemic heart disease, heart failure, and stroke, and in various other disorders including diabetes, cognitive decline and dementia, reproductive disorders such as polycystic ovary disease and endometriosis, immunological-inflammatory diseases such as asthma and rheumatoid arthritis, psoriasis, ophthalmologic disorders such as macular degeneration and diabetic retinopathy, chronic obstructive pulmonary diseases, and several neoplastic diseases (19).

Wound healing
Skin wound healing starts immediately after injury and consists of three phases: inflammation, proliferation, and maturation. These phases proceed with complicated but well-organized interactions between various tissues and cells. Wounding can destroy blood vessels and create a hypoxic environment because of poor perfusion, and therefore provides an appropriate environment for hypoxia inducible factor alpha stabilization. At the first phase of wounding, induced hypoxia leads to rapid infiltration of inflammatory cells including neutrophils, mast cells, lymphocytes, and macrophages. The formation of granulation tissue, which is necessary for the last phase of wound healing, starts at the wound space approximately four days after injury. Numerous new capillaries endow the new stroma with its granular appearance. Macrophages, fibroblasts, and endothelial cells move into the wound space at the same time. Macrophages not only augment inflammatory responses but also secrete VEGF and FGF, eventually promoting angiogenesis (20, 21).

Proangiogenic roles of macrophages in diabetic wounds are similar to those in wounds inflicted by physical injuries. However, severe hypoxia in diabetic wounds often fails to directly trigger effective angiogenesis because of significant cell death under such conditions. As a practical conclusion, the hypoxia inducible factor pathway offers promising therapeutic targets to promote angiogenesis in wounds (20) (1).

Diabetes and its related complications
Hiroaki Kakizawa et al. (22) reported that plasma VEGF concentrations are higher in diabetic patients who are hospitalized because of poor glycemic control than in healthy subjects. According to them, the increased plasma VEGF concentrations declined along with decreases in fasting plasma glucose and
hemoglobin A1c (HbA1c) as a result of treatment. The significant and independent correlation between plasma VEGF concentrations and HbA1c suggests that chronic hyperglycemia may increase plasma levels of VEGF, and that reduction of high VEGF levels may be possible by improvement of glycemic control (23). Prolonged hyperglycemia activates the sorbitol pathway and induces intracellular anaerobic conditions and hemodynamic change (24). These conditions may facilitate the production of VEGF that may contribute to diabetic vascular complications and arteriosclerosis. Interestingly, the increase in VEGF production has a reverse correlation with the reduction of hyperglycemia. Santilli et al. (25) suggested increased serum VEGF levels as a predicting risk factor for the development of persistent microalbuminuria in young type 1 diabetic patients. Another study indicates that VEGF mRNA and urinary excretion of VEGF are increased in diabetic nephropathy (26).

Most diabetic patients, especially those with poor glycemic control, develop diabetic retinopathy, which remains the major cause of new-onset blindness among diabetic adults. Diabetic retinopathy is characterized by vascular permeability and increased tissue ischemia and angiogenesis.

VEGF has initially drawn much attention as an important mediator of retinal ischemia– associated intraocular neovascularization (4, 6, 10). VEGF is produced from many cell types within the eye and past studies have shown that VEGF levels are markedly elevated in vitreous and aqueous fluids in the eyes of individuals with proliferative diabetic retinopathy (PDR). Recently there has been success in the treatment of diabetic retinopathy as well as other ocular vasculopathies with anti-VEGF medication. Bevacizumab (Avastin, Genentech, South San Francisco, CA) is a recombinant, humanized monoclonal anti-VEGF antibody that binds all VEGF isoforms and exerts its neutralizing effect by inhibiting the VEGF–receptor interaction, thus blocking both increased vascular permeability and angiogenesis. The drug was approved by the United States Food and Drug Administration initially for intravenous use for metastatic colorectal cancer. Bevacizumab has been administered off label for the treatment of neovascular age-related macular degeneration and other retinal vascular conditions with encouraging results (6).

**Hypertension**

VEGF-A is highly expressed by renal glomerular epithelial cells (podocytes) and plays an important role in the formation of the glomeruli during development (27), but curiously is also highly expressed within the adult glomerulus despite little or no angiogenesis occurring beyond development. VEGF isoform expression in glomeruli is heterogeneous. Individual human glomeruli express one, two, or all three of these (VEGF_{121}, VEGF_{165}, VEGF_{189}) main isoforms at the mRNA level. VEGF_{189} and VEGF_{165} are most predominantly found in the renal glomerulus. Minor VEGF mRNA splice variants (VEGF_{206}, VEGF_{183}, VEGF_{189}, and VEGF_{165}) have also been reported, but are less well characterized than the three main isoforms (28).

**Obesity and metabolic syndrome**

Adipose tissue is considered as the largest endocrine gland because it produces free fatty acids, hormones, growth factors, and cytokines such as leptin, adiponectin, resistin, VEGF, insulin growth factor (IGF-1), interleukin-6 (IL-6), and tumor necrosis factor-alpha (TNF-α) (29). Epidemiological studies show that the visceral fat accumulation “the predominant driving force behind the metabolic syndrome MetS” (30) is the most important determining factor for VEGF circulating levels. During embryogenesis, adipose tissue development is spatially and temporally associated with microvessel growth. In developing embryos, the formation of primitive fat organs occurs at the perivascular site (29). Endothelial cells isolated from different adipose tissues differ in their proliferative capacity, which suggests that adipocytes play both guidance and maintenance roles in vascular development. A recent study suggests that adipocytes and their accompanying endothelial cells might share a common progenitor that could differentiate into adipocytes or endothelial lineages depending upon exposure to different environments (29) (145). Accumulating evidence shows that capillary endothelial cells communicate with adipocytes via paracrine signaling pathways, extracellular components, and direct cell-cell interactions (31).

Adipose tissue has been long known to promote wound healing and revascularize ischemic tissues including myocardium (31). These findings suggest that adipose tissue produces angiogenic molecules (31). Experimental angiogenesis assays show that
conditioned media obtained from preadipocytes and tissue homogenates from omentum or subcutaneous fat induce angiogenesis in chick chorioallantoic membrane (CAM) and mouse cornea (31). It seems that bone marrow-derived circulating endothelial precursor cells do not significantly participate in adipose neovascularization, although these cells are known to contribute to neovascularization in other tissues. For instance, VEGF is a potent chemotactic factor for inflammatory cells and contributes to mobilization of bone marrow-derived circulating endothelial precursor cells, which are involved in tumor neovascularization. Interestingly, expression levels of VEGF are only moderately up-regulated in growing adipose tissue although VEGF is a main angiogenic factor in omentum (29).

In rapidly extending adipose tissue, hypoxia is another important factor for vascular growth and remodeling. In response to hypoxia, adipose tissues produce hypoxia inducible factor 1α–induced angiogenic factors such as VEGF, leptin, TNF-α, and PAI-1, which regulate angiogenesis and vasculogenesis (32). Thus it is reasonable to speculate that expansion of adipose tissue is associated with local hypoxia, which contributes to angiogenesis by induction of a number of growth factors.

Leptin is an adipocyte-derived hormone that regulates food intake and energy homeostasis. Functional impairment of leptin leads to severe obesity, diabetes, and infertility. Interestingly, leptin is also defined as a potent angiogenic factor. In addition to its direct angiogenic activity, leptin up-regulates VEGF mRNA expression via activation of the Jak/Stat3 signaling pathway (33). Among all adipose tissues examined in the body, omentum expresses the highest level of VEGF (29). Localization studies have shown that adipocytes are the primary source of VEGF, which may act as an angiogenic and vascular survival factor for the omental vasculature. Additionally, adipose- infiltrated inflammatory cells and adipose stromal cells also significantly contribute to VEGF production (29). Anatomically, visceral adipose tissue, which is the main indicator of waist circumference, is present mainly in the mesentery and omentum, and drains directly through the portal circulation to the liver (34).

Several documents indicate that serum VEGF concentrations are positively correlated with body mass index (BMI) and visceral obesity (35, 36). Michaela Loebig et al. (37) reported a positive correlation between plasma VEGF concentrations and BMI over a large range of BMI groups in a healthy population. They also demonstrated significantly higher concentrations of plasma VEGF in obese subjects than in normal and low weight individuals.

Lian-Yu Lin et al. (38), in their proposed model, demonstrated that obesity directs to an inflammatory process, which could be the precursor of MetS components including insulin resistance, dyslipidemia, and hypertension.

Gaby Kressel et al. (39) investigated the relationship between vascular and systemic markers of low-grade inflammation such as high sensitive c-reactive protein (hs-CRP), soluble vascular adhesion molecule 1 (sVCAM-1), soluble intracellular adhesion molecule-1 (sICAM-1), plasminogen activating inhibitor-1(PAI-1), fibrinogen, and cardiovascular traditional risk factors and the MetS.

It seems that the study of the association of circulating VEGF with MetS in human samples has only recently begun; therefore, documentable reports in this field are scarce (40-43). However, a few reports have shown an association of circulating VEGF with the MetS, as well as with a number of its components (40, 41). Some evidence indicates the associations of some single nucleotide polymorphisms (SNPs) with MetS via a genome-wide association study (44) and candidate gene approach (45, 46). It is not yet clear whether the elevated VEGF level is a deleterious factor or a physiologic/negative feedback response to prevent the progress of ischemia in metabolic linked ischemia as well as MetS.

**Atherosclerosis**

From endothelial dysfunction to plaque rupture, VEGF directly and indirectly attracts inflammatory cells into the intima in various stages of atherogenesis. Human monocytes express the receptor VEGFR-1 (flt-1), and administration of VEGF has been shown to significantly increase the number of mature macrophages in the arterial endothelium within weeks. This accumulation of macrophages was associated with increased total plaque size. VEGF primes endothelial cells to secrete increased amounts of E-selectin, an adhesion molecule necessary for trans-epithelial migration of leukocytes. Endothelial cells “pretreated” with VEGF also produce significantly higher amounts of tissue factor after TNF-α exposure.
than cells exposed to TNF-α alone. If the plaque contents later become exposed, the accumulation of tissue factor could increase the risk of a thrombotic event. Not surprisingly then, serum VEGF level has been shown to predict adverse cardiac events in patients with known atherosclerosis (47). For example, men with unstable angina and serum VEGF concentrations ≥0.3 pg/L were 2.5 times more likely to die of myocardial infarction within six months of cardiac event than those with serum VEGF levels <0.3 pg/L (48).

Herosclerosis, localized hypoxia and oxidative stress in the vessel wall accelerates activation of HIF-1α and expression of VEGF (49). Subsequent intra-plaque angiogenesis leads to neovascularization of the plaque vasavasorum, leaky capillaries, hemorrhage, and progression to a vulnerable plaque phenotype.

VEGF plays an important role in this cascade by not only stimulating the formation of new intra-plaque capillaries, but also attracting macrophages and T lymphocytes into the subintimal space (49, 50). These cells further produce pro-angiogenic factors such as IL-8, TNF-α, IL-17, and more VEGF (50). When fragile new intra-plaque capillaries bleed, macrophages phagocytize the lipid-rich debris, become foam cells, and eventually add to the plaque’s necrotic core (50-52). Taken together, the contribution of VEGF to atherogenesis has been challenged.

Fig. 2. VEGF involved in several physiological and pathological conditions

1) Breast, colorectal, prostate, gastric, esophageal, hepatic, ovarian cancers, and hematologic malignancies. 2) Alzheimer, multiple sclerosis, age related macular degeneration. 3) Rheumatoid arthritis, psoriasis, Behjat disease and systemic sclerosis. 4) Hypertension, obesity, diabetes type 2 (diabetic retinopathy and nephropathy), hyperlipidemia, MetS. 5) Chronic obstructive pulmonary diseases such as chronic bronchitis and emphysema. 6) Response to ovulation, placentation, embryonic development, wound and bone fracture healing. 7) Pre-eclampsia, endometriosis.
