Molecular Analysis and Expression of \textit{bap} Gene in Biofilm-Forming Multi-Drug-Resistant \textit{Acinetobacter baumannii}

Omid Azizi\textsuperscript{1}, Fereshteh Shahcheraghi\textsuperscript{2}, Himen Salimizand\textsuperscript{3}, Farzan Modarresi\textsuperscript{4}, Mohammad Reza Shakibaie\textsuperscript{*1,5,6}, Shahla Mansouri\textsuperscript{1}, Rashid Ramazanzadeh\textsuperscript{7}, Farzad Badmasti\textsuperscript{2}, Vajihe Nikbin\textsuperscript{2}

\textbf{Background:} \textit{Acinetobacter baumannii} is commonly resistant to nearly all antibiotics due to presence of antibiotic resistance genes and biofilm formation. In this study we determined the presence of certain antibiotic-resistance genes associated with biofilm production and the influence of low iron concentration on expression of the biofilm-associated protein gene (\textit{bap}) in development of biofilm among multi-drug-resistant \textit{A. baumannii} (MDRAB).

\textbf{Methods:} Sixty-five MDRAB isolates from clinical samples were collected. Molecular typing was carried out by random amplified polymorphism DNA polymerase chain reaction (RAPD-PCR). Biofilm formation was assayed by the microtiter method.

\textbf{Results:} The sequence of \textit{ba}p was determined and deposited in the GenBank database (accession no. KR080550.1). Expression of \textit{bap} in the presence of low iron was analyzed by relative quantitative real time PCR (rqRT-PCR). Nearly half of the isolates belonged to RAPD-types A and B remaining were either small clusters or singleton. The results of biofilm formation revealed that 23 (35.4%), 18 (27.7%), 13 (20%), and 11 (16.9%) of the isolates had strong, moderate, weak, and no biofilm activities, respectively. \textit{ompA} and \textit{csuE} genes were detected in all, while \textit{bap} and \textit{bla}\textsubscript{PER-1} were detected in 43 (66%) and 42 (64%) of the isolates that showed strong and moderate biofilm activities (p ≤ 0.05), respectively. Analysis of \textit{bap} expression by rqRT-PCR revealed five isolates with four-fold \textit{bap} overexpression in the presence of low iron concentration (20 \textmu M).

\textbf{Conclusion:} The results suggest that \textit{bap} overexpression may influence biofilm formation in presence of low iron concentration.

\textbf{Keywords:} \textit{Acinetobacter baumannii}, Biofilm, Biofilm-associated Protein (\textit{bap}), Iron, rqRT-PCR

\textbf{Introduction}

\textit{Acinetobacter baumannii} has gained considerable importance in the last decade due to its extensive antibiotic resistance and biofilm formation in hospitals worldwide (1, 2). Resistance of \textit{A. baumannii} to different antibiotic classes is mainly mediated by biofilm formation; a specific antibiotic-resistance gene may not exist in this organism (3). Microbial biofilm is a community of one or more organisms attached to sessile substrates or live organs (4). Biofilm formation is thought to be an important pathogenic feature of \textit{A. baumannii}, especially in cases of ventilator-associated pneumonias and catheter-related urinary tract infections, as it facilitates the survival of the bacterium in hostile environments (5).
Common factors that influence biofilm formation are nutrient availability, the presence of outer membrane proteins and pili, and macromolecular secretions such as extracellular DNA (eDNA) (6). It has been shown that a blood stream isolate of A. baumannii produces a protein related to a staphylococcal biofilm-associated protein (Bap), which is also required for the development of biofilms on abiotic surfaces (7). Members of the Bap family are high-molecular weight proteins that present on bacterial cell surfaces (8).

The ability of A. baumannii to form biofilms is also largely dependent on pili, which mediate attachment and biofilm formation. Similarly, csuE, is a member of the usher-chaperone assembly system. The genes are cluster together in form of the csu operon, the products of which form a pilus-like bundle structure in this bacterium (9). This gene has proved to be an important factor of A. baumannii biofilm formation (10).

Among the outer membrane proteins identified in A. baumannii, OmpA (AbOmpA) is the most abundant surface protein (11). AbOmpA acts as a porin, is required for eukaryotic cell adhesion, and partially contributes to serum resistance and biofilm formation (12).

Biofilm formation in A. baumannii occurs in three stages; early development, matrix formation, and maturation (13). It has been shown that iron uptake contributes to biofilm formation. In Pseudomonas aeruginosa, intracellular iron levels are important in the first stage of biofilm formation (14). N-(3-oxododecanoyl)-L-homoserine lactone (AHL-12) activates defense-relevant functions of phagocytic cells, including enhancement of phagocytosis, increased expression of adhesion receptors, and induction of chemotaxis. This leads to the hypothesis that early recognition of developing biofilms might be the key to a successful host defense against biofilm infections (15). In Stenotrophomonas maltophilia, iron restriction induces biofilm formation; three-dimensional reconstructions obtained from confocal stacked images using the Image J program revealed that the amount of biofilm produced by fur mutant cells under iron-depleted conditions was greater than that of the wild type strain, and the addition of an iron chelator had no effect on biofilm production (16).

Similar observations were previously reported for Legionella pneumophila and Staphylococcus aureus (17, 18).

Little information exists regarding the effect of iron concentration on bap expression in Acinetobacter; we reported previously that low iron plays an important role in biofilm formation by increasing the production of the autoinducer N-acyl homoserine lactone (AHL) (19). As the iron concentration decreased the amounts of siderophore and biofilm increased. Recently we showed that limited iron concentration results in overexpression of the adeABC efflux pump and luxI and luxR quorum-sensing genes in clinical isolates of A. baumannii (20).

The aim of the present study was to evaluate the presence of certain antibiotic-resistance genes and influence of low iron concentration on bap expression and biofilm formation in multi-drug resistant A. baumannii (MDRAB).

Materials and Methods

Hospitals setting and bacterial isolation

From February to August 2013, 65 non-duplicate MDRABs were isolated from hospitalized patients in intensive care units (ICUs) of general hospitals A and B in Kerman, in southeast Iran. Hospital A has a pediatric, a neonatal, and an adult ICU. Hospital B has three ICUs with no age categories. Patients frequently transfer between the two hospitals. If multiple isolates were obtained from an individual, one was randomly selected for inclusion. The collected samples from both hospitals were inoculated on cysteine electrolyte-deficient (CLED) (Hi-Media, Mumbai, India) and Luria-Bertani (LB) agar (Merck, Darmstadt, Germany) medium and incubated overnight at 37 °C. Isolated colonies were then subjected to conventional diagnostic tests and identified to the species level by the API-20 NE (BioMérieux, Marcy-l’Etoile, France) system and the presence of blaOXA-51 gene by PCR.

Antimicrobial susceptibility testing

Antimicrobial susceptibility of all the isolates was determined by the disk diffusion break point assay according to Clinical and Laboratory Standards Institute (CLSI) guidelines (21). All antibiotic disks were purchased from MAST Co. Ltd, UK and used as per manufacturer descriptions. The following
antibiotics disks were used in this study (concentration µg/ml): amikacin (AN: 30 µg), tetracycline (TE: 30 µg), gentamicin (GM: 10 µg), nalidixic acid (NA: 30 µg), levofloxacin (LE: 5 µg), cefotaxime (CTX: 30 µg), piperacillin (PIP: 100 µg), ciprofloxacin (CIP: 5 µg), amoxicillin + clavulanic acid (AMC: 30 µg), tobramycin (TOB: 10 µg), ceftazidime (CAZ: 30 µg), ceftazidime (CAZ: 30 µg), imipenem (IMP: 10 µg), and meropenem (MEM: 10 µg) with an inoculum of 10^4 CFU per spot. The minimum inhibitory concentrations (MICs) of ciprofloxacin, gentamicin, piperacillin/tazobactam, cefotaxime, ceftazidime, imipenem, and colistin were determined using the E-test (Mast Co. Ltd, UK). The results were interpreted according to the CLSI guidelines. A reference strain of Escherichia coli ATCC 25922 was used as a quality control.

Detection of bap, csuE, blaPER-1, and ompA by PCR
All isolates were initially inoculated in LB agar and incubated overnight at 37 °C. DNA was extracted from isolated colonies with a genomic DNA extraction kit (Thermo Scientific, Vilnius, Lithuania) according to the manufacturer’s instructions, and used as the DNA template in all amplifications. The biofilm-formation-related genes bap, csuE, ompA, and blaPER-1, were amplified by conventional PCR (10). A list of primers, their sequences, annealing temperatures, and sizes of the amplified products used in this study are shown in Table 1.

Table 1. List of primers, their sequences, annealing temperatures, and sizes of the amplified products used in this study.

*Primers were designed by AlleleID software (v 7.5, Premier Biosoft International, Palo Alto, CA, USA).

bap sequencing
PCR products of bap were sent to Macrogen Inc., Seoul, Korea, for sequencing using an ABI prism 3730/3730x (Applied Biosystems, Foster City, CA, USA) DNA Analyzer. The 1449 bp bap amplicon was sequenced using the same primers used for the PCRs. The sequence was analyzed using the BLAST alignment search tool (http://www.ncbi.nlm.nih.gov/BLAST) and manually assembled using CLC main workbench software, version 5.5 (CLC Bio, Aarhus, Denmark). The bap sequence was deposited in GenBank under accession number KR080550.1.

Molecular typing by random amplified polymorphism DNA technique
The molecular typing was done by the random amplified polymorphism DNA (RAPD) technique using primers DAF4 (5’-CGGCAGCGCC-3’) and M13 (5’-GAGGGTGCGCGTTCT-3’) [25]. RAPD profiles were used to measure clonal relationships among A. baumannii isolates. Primers were purchased from Generay Biotech (Co., Ltd, Shanghai China). A 1-kb DNA ladder (Life Technologies, Gibco BRL, Breda, Netherlands) as molecular size standards, a positive control consisting of A. baumannii ATCC 19606 DNA,
previously amplified using primer DAF4, and a negative control, which contained all the reaction components except template DNA, were included on the gels. Banding patterns were analyzed by the unweighted pair-group method with arithmetic averages (UPGMA) clustering using Gel Compare II software, version 4.0 (Applied Maths, Sint-Matens-latem, Belgium). Isolates with 96% or greater similarity were considered as identical, and a cut-off value of 80% similarity was used for clustering. The RAPD-PCR was repeated to confirm the results and 98.6% homology was obtained.

**Biofilm formation measurement**

Biofilm formation was quantified by the microtiter plate assay method as described previously (22). Briefly, *A. baumannii* strains were grown overnight in LB broth with 0.25% glucose (LBG) at 37 °C. The culture was diluted 1:50 in freshly-prepared LBG pre-warmed to 37 °C. Then, 200 ml of suspension was used to inoculate wells of sterile 96-well polystyrene microtiter plates, followed by incubation at 37 °C for 72 h. After three washes with phosphate-buffered saline (PBS), any remaining biofilm was stained with crystal violet 1% (w/v) for 25 min and wells were washed again with PBS. The dye bound to the adherent cells was resolubilized with 200 ml of ethanol/acetone (80:20, V/V) and the optical density (OD) was quantified at 570 nm using an ELISA reader (Synergy4; BioTek). Each assay was performed in triplicate. The adherence capabilities of the test strains were classified into four categories: three standard deviations (SDs) above the mean OD of the negative control (broth only) was considered as the cut-off optical density (ODc). Isolates were classified as follows: if OD ≤ ODc, the bacteria were non-adherent; if ODc < OD ≤ 2 × ODc, the bacteria were weakly adherent; if 2 × ODc < OD ≤ 4 × ODc, the bacteria were moderately adherent; if 4 × ODc < OD, the bacteria were strongly adherent.

**RNA extraction and relative quantitative real-time PCR of bap**

RNA was extracted from isolated colonies with an AccuZol kit (Bioneer, Seoul, Korea) as described previously (20). Briefly, for amplification, 1 μl of each primer (Table 1), 25 μl of AccuPower® 2X Green Star Master Mix solution (Bioneer, Seoul, Korea), 1 μl of ROX dye, and 5 μl of cDNA template were added. Quantification of specific *bap* genes was performed using the real time PCR system (ABI Step One™, USA) with the following cycle profile: 1 cycle at 95 °C for 2 min followed by 35 cycles at 95 °C for 25 s, annealing at 55 °C for 5 min, and extension at 72 °C for 20 s. Real-time PCR performance was confirmed to be reproducible at the threshold cycles (Ct) < 35. To determine the sensitivity and specificity of the primers, *A. baumannii* ATCC 19606 DNA was serially diluted from 100 ng to 1 fg and used as standards. In addition, one melting curve cycle was performed on the SYBR channel at gain 70 using a ramping rate of 0.5 °C/10 s for 65-95 °C. Melt (65-95 °C), hold 6 s on the 1st step, and hold 5 s on the next steps. The PCR amplification and one melting curve cycle were analyzed and optimized using Rotor Gene software (Qiagen) as described by the manufacturer. The experimental points were aligned in a straight line and correlation coefficients (R) ascertained at 0.91658 (R2 = 0.84), and the following calibration equation was obtained: y = 0.34908x + 29.66623. The slope of 0.34908 corresponded to an amplification efficiency of 99.8%. The Tm value of the *bap* products was 87 °C ± 0.0. Relative *bap* expression was calculated as a fold change (RQ) between the target genes and the matched reference 16SrRNA gene mRNA as follows: RQ = 2^(-∆∆Ct), where Ct equals the difference between the Ct values for the analyzed gene and Ct for the 16SrRNA reference gene amplifications in 50 μM concentration as control and 20 μM tests. The primers used for real-time PCR are listed in Table 1.

**Effect of iron on bap expression**

Relative quantitative real-time PCR (rqRT-PCR) was performed to compare the effect of iron at concentrations of 20 μM as test and 50 μM as control on *bap* expression (20). Briefly, 1 × 10^6 CFU/mL of bacterial cells were inoculated into two separate 10 mL volumes of iron-limiting M9 medium with 20 and 50 μM FeCl₃ (Merck, Darmstadt, Germany), and incubated at 37 °C overnight with shaking at 200 rpm. The bacterial suspension was centrifuged at 10,000 rpm for 6 min at 4 °C and RNA was extracted from the cell pellet. Pearson’s χ2 or Fisher’s exact tests were performed to compare the number of isolates that overexpressed *bap* gene.
**Statistical analysis**
Each value was expressed as a mean ± SD. SPSS software 17 (SPSS Inc., Chicago, IL, USA) was used for statistical analysis. The prevalence of MDR and genes were compared using chi-squared or Fisher’s exact tests. A p-value ≤ 0.05 was considered statistically significant for two-tailed tests. For descriptive statistics we calculated percentage, frequency, mean and median values, and 95% confidence intervals (95% CI).

**Results**

**Demographic Analysis and Antimicrobial Susceptibility Testing**

Sixty-five MDRABs were isolated from hospitalized patients in ICUs of two general hospitals (A and B) in Kerman, in southeast Iran. Twenty-eight (43.1%) of the isolates were recovered from sputum and bronchial alveolar lavage specimens of patients admitted with pulmonary and lower respiratory tract infections. Also, 18 (27.7%) of the isolates were collected from urine, 5 (7.7%) from blood, and 14 (21.5%) from patients who had undergone surgical procedures. Demographic information showed that 25 (38%) of the patients in the ICUs were ≤ 50 years of age, 12 (18.5%) had received either cephalosporins or aminoglycoside antibiotics, and 17 (26.2%) had underlying diseases such as diabetes or cancer. Forty-two patients (65%) were male and 23 (35%) were female.

The disk diffusion susceptibility testing revealed that all 65 (100%) of the isolates were resistant to piperacillin, cefixime, ciprofloxacin, levofloxacin, ceftazidime, and gentamicin, ticarcillin and 53 (81%) were resistant to imipenem. However, 56 (86.2%) of the isolates were susceptible to colistin (MIC\(_{90}\) = ≥ 4 μg/ml), according to E-test results (Table 2). All 65 isolates (100%) were defined as MDR based on their resistance to more than three antibiotic classes.

**Molecular typing by RAPD-PCR**

To determine the genetic diversity of A. baumannii isolates and explore its putative relationship with biofilm formation and antibiotic resistance, all 65 isolates were analyzed by RAPD-PCR genotyping using the primers shown in Table 1. On the basis of RAPD profiles in agarose gels, the number of bands ranged from 10 to 19 and the bands ranged in size from 200–2000 bp (Fig. 1). Control samples for RAPD-types A and B were included in the gel to enable interpretation. Dendrogram analysis and clonal relationships of A. baumannii isolates revealed ten different RAPD types (Fig. 2).

Twenty-five isolates classified as RAPD-type A. The clonal lineages of RAPD-type A were 95% related and the band patterns indicated similar genetic backgrounds. This result indicates the possible spread of clones belonging to this cluster in the ICU of hospital A. Nine isolates classified as RAPD-type B and three isolates classified as RAPD-type C and D comprised most of the isolates from hospital B and were 62% similar to clones from RAPD-type A. Other isolates were either singleton (not related to any RAPD-type) or were small RAPD-type groups containing two identical clones.

Biofilm formation assay and distribution of biofilm associated genes

Biofilm development revealed that 23 (35.4%), 18 (27.7%), 13 (20%), and 11 (16.9%) isolates had strong, moderate, weak, and non-adherent activity in the microplate assay, respectively (Fig. 3 and Table 2). We found that the measurements were consistent between the triplicate assays but varied considerably between isolates. PCR was performed to measure gene frequencies associated with biofilm formation, including bap (1449 bp), csuE (168 bp), blaPER-1 (925 bp), and ompA (578 bp). All 65 isolates encoded ompA and csuE, while 43 (66.2%) and 42 (64.6%) isolates encoded bap and blaPER-1, respectively, and those isolates belonged to RAPD-type A (Table 2). bap and blaPER-1 were mainly detected in the isolates showing high biofilm activity. Correlations of RAPD-type, duration of stay, underlying diseases, presence of bap, PER-1, csuE, ompA genes, biofilm intensity, and minimum inhibitory concentrations (MICs) to colistin are shown in Table 3. Interestingly, bap was not detected in the isolates that did not produce biofilm. Amplification of bap from A. baumannii strains exhibiting strong biofilm activity was confirmed by DNA sequencing and the sequence was deposited in the GenBank database with the accession number KR080550.1.

Expression of bap gene in low iron

The results were normalized with 16SrRNA as a reference gene and the fold-change increase was measured by $RQ = 2^{\Delta \Delta Ct}$. Fig. 4 shows bap expression in the A. baumannii population grown in iron-limiting medium (M9 medium with 20 μM FeCl₃). The result was compared with control strain A. baumannii ATCC 19606. In some A. baumannii isolates that exhibited strong biofilm formation, bap expression in 20 μM Fe was fourfold greater than in the same isolates grown in 50 μM Fe.

Discussion

The ability of A. baumannii to persist in dry environments is a consequence of biofilm formation, and the presence of various antibacterial resistance genes makes this bacterium a successful pathogen among nosocomial bacteria (26). In A. baumannii the formation and maturation of biofilms depend on the complex interplay of environmental factors and cell-associated properties (27, 11). No information exists on the role of iron in bap expression and biofilm development in this bacterium; therefore, in this study we focused on the role of four biofilm-associated genes, bap, csuE, blaper-1, and ompA, and the effect of iron on bap expression and biofilm formation. Rodriguez-Baño et al., (28) showed that biofilm-forming A. baumannii isolates were more susceptible to imipenem and ciprofloxacin than non-biofilm-forming counterparts, which suggests that the survival of these isolates in the hospital environment was less dependent on antibiotic resistance than on biofilm formation.

In the present study we found that A. baumannii isolates were resistant to drugs commonly used to treat A. baumannii. These drugs include cephalosporins, beta-lactam and beta-lactamase inhibitors, carbapenems, fluoroquinolones, aminoglycosides, tetracyclines, and rifampicin. We observed that the isolates that carried the blaper-1 extended-spectrum-resistant gene formed a significantly greater amount of biofilm than those that lacked blaper-1 ($p \leq 0.05$). Molecular analysis showed that 43 (66.2%) of the clinical isolates of A. baumannii in the current study encoded bap and formed strong biofilms ($p \leq 0.05$). Isolates that overexpressed bap and formed strong biofilms belonged mostly to RAPD-type A. Our PCR result was confirmed by sequencing bap gene. In the high-quality draft genomes AFDB, AFDK, AYOH, JFEL, and JFXM, bap coding sequences resided in one contig, but were interrupted by stop codons and split into two or more open reading frames (ORFs), as in many wholly sequenced genomes. Lee et al., (10) and Badmasti et al., (22) suggested that biofilm formation in A. baumannii was related to PER-1 production. A possible explanation for this significant characteristic of A. baumannii could be...
that _blaPER-1_ may increase the adhesion of cells that carry this gene without necessarily contributing to biofilm formation as previously reported (29). It has been shown that micronutrients, including iron, may change the properties of _A. baumannii_ cells, such as whole-cell hydrophobicity and altered bacterial cell-cell signaling, which can retard biofilm formation. This may explain why, for example, we observed some _bap_ isolates with moderate biofilm activity.

To determine whether _bap_ expression is actually regulated by the iron concentration, we performed qRT-PCR of _bap_ in low iron. Indeed, in 20 µM iron, biofilm formation in strains with _bap_ was significantly greater than in strains without _bap_ (p ≤ 0.05). These data were supported by microscopic visualization of biofilms of three randomly-selected _A. baumannii_ isolates that contained _bap_ and exhibited strong biofilm formation, and suggest that the low iron concentration may play a role in early biofilm formation. Eijkelkamp _et al._, (27) reported that in _A. baumannii_, under low iron conditions, transcription levels were more than 2-fold up-regulated for 463 genes, including 95 genes that were up-regulated more than 4-fold, some of which are critical to the virulence of relevant pathogenic strains, were up-regulated more than fourfold. Similarly, _A. baumannii_ ATCC 19606 formed more biofilm on a plastic surface when cultured in a chemically-defined medium under iron-chelated conditions. In another investigation, the addition of 40 µM FeCl₃ to M9 minimal medium resulted in a greater number of attached cells than were seen in iron-free M9 (26).

We also found that nine (13.8%) of the _A. baumannii_ isolates were resistant to colistin. Interestingly, most of the isolates were also resistant to imipenem. In nonfermenters, such as _A. baumannii_, resistance to colistin is rarely reported and demonstrates the gravity of emergence and the spread of new strains with pan-drug resistant (PDR) phenotypes. Such refractory isolates are problematic, because no other drugs are effective against this bacterium. Seven of the colistin-resistant isolates were placed in RAPD-type A and all were isolated from hospital A, which shows clonal distribution of this genotype.

From data presented in this study, we conclude that biofilm formation and quantity are influenced by _blaPER-1_ and _bap_ genes. The data also revealed that iron limitation affected _bap_ expression in early stages of biofilm formation in certain isolates of _A. baumannii_.
